(54) Title: END-TO-END BANDWIDTH ESTIMATION FOR CONGESTION CONTROL IN PACKET SWITCHING NETWORKS

(57) Abstract: The invention herein described consists of an algorithm, which performs an end-to-end estimation of the bandwidth available in an end-to-end connection established between a server and a client via a packet switching network such as a the Internet Protocol Network (IP). This algorithm is used to properly regulate the input rate at the send side. Typical applications are delivering best effort traffic over TCP, or audio and video traffic over RTP/UDP. The invention is particularly effective over wireless Internet and can be used in a content delivery system to dynamically choose the best server between a set of servers to satisfy the request of a client, or to select the best route in a content deliver or global hosting system.

WO 02/33889 A2

## END-TO-END BANDWIDTH ESTIMATION FOR CONGESTION CONTROL IN PACKET SWITCHING NETWORKS

5 This application is based on Provisional Application No. 60/240,855, filed Oct. 17  
2000 in the United States of America. This application includes matter protected by  
copyright.

### BACKGROUND OF THE INVENTION

#### 1. Technical Field

10 This invention relates generally to efficient communication over packet switching  
networks. More particularly, the invention relates to a novel method for performing an end-  
to-end estimation of available bandwidth and a congestion control in packet networks such  
15 as the Internet. The invention addresses the issues of improving the efficiency in  
transferring data, audio and video over of the wireline and wireless Internet.

#### 2. Description of the Related Art

20 The Internet Protocol connects all variety of different networks. An IP network  
implements a simple store-and-forward service. Over the IP network there are two  
transport protocol: the Transmission Control Protocol (TCP) and the User Datagram  
Protocol (UDP). The TCP is a sophisticated and complex protocol that offers a reliable,  
connection-oriented, end-to-end byte-stream service. It contains sophisticated  
algorithms of flow and congestion control in order to manage resource sharing and  
avoid congestion phenomena. Congestion control functions were introduced into the  
25 TCP in the late 1980s after the TCP/IP had become operational, and the network was  
suffering from congestion collapse. TCP congestion control has been introduced and  
described by V. Jacobson in his papers. Van Jacobson's seminal paper defines an  
additive increase/multiplicative decrease algorithm for throttling the size of the  
congestion window. The key idea is to probe the network capacity by increasing the  
30 load until packet loss is experienced. When a loss is experienced, the window size is  
reduced. More precisely, first *cwnd* is increased until packet losses are experienced and  
then it is rapidly decreased. The increasing process goes through two phases called *slow  
start* and *congestion avoidance*. During the slow start phase *cwnd* is exponentially  
increased until the *slow start threshold* (*ssthresh*) value is reached. This phase is  
35 intended to quickly grab available bandwidth. After the *ssthresh* value is reached, the  
*cwnd* is linearly increased to gently probe for extra available bandwidth. This phase is  
called *congestion avoidance*. At some point the TCP connection starts to lose packets.  
After a timeout is experienced, the window is drastically reduced to one and the slow  
start/congestion avoidance cycle repeats. This behavior is known as TCP Tahoe. Since  
40 during the slow start phase the network can be strongly underutilized, two other  
algorithms, called *fast retransmit* and *fast recovery*, were introduced to minimize the  
number of timeouts. The implementation of these algorithms provides what is currently  
called TCP Reno. *Fast retransmit* and *fast recovery* are both triggered after the sender  
receives three DUPACKs. The algorithm of *fast retransmit* sends again the packet that  
45 was acknowledged three times. The algorithm of *fast recovery* reduces the congestion  
window to half and enters into congestion avoidance phase. After a time out, the  
Congestion window is reduced to one.

Today TCP Reno is the more widely version employed. It is used in the leading

Unix, Linux TCP protocol suite or in the Microsoft Windows TCP® protocol suite.

TCP was originally designed to provide reliable data delivery over conventional wireline networks for a limited range of transmission rates and propagation delays. Nowadays, communication paths with ever-larger bandwidth×delay product, wireless links, quality of service (QoS) requirements for interactive communication are all shifting the domain for which TCP was originally engineered.

We list here main modifications proposed for TCP Reno. TCP with selective acknowledgments (TCP SACK) introduces a more refined algorithm for acknowledging data. TCP New Reno introduces a algorithm for recovering from many losses in a window of data.

A new congestion control algorithm is known as TCP Vegas. It throttles the congestion window based on the difference between the Actual Rate and the Expected rate. This algorithm has never been deployed in the TCP protocol suite of Microsoft or other commercial operating systems or in the Unix or Linux operating systems.

Today the TCP has a major performance problem over unreliable links such as wireless links that are often characterized by sporadic high-bit error rates, and intermittent connectivity due to handoffs. In fact, a loss due to an unreliable link is misinterpreted as a symptom of congestion by current TCP schemes and thus leads to an unnecessary shrinking of the control windows (i.e. the slow start and congestion window) with a consequent throughput reduction. It is well-known that TCP experiences a very low performance over wireless links such as in the GSM, GPRS, 3G, 4G, or UMTS systems. Analogously, it is also very well-known that TCP is not able to use the bandwidth of satellite links, which are characterized by large delays and random loss.

Recently, several schemes have been proposed to mitigate the negative effect on TCP performance of sporadic loss due to wireless links. These schemes can be classified into three groups: end-to-end proposals, split connection proposals and link layer proposal. End-to-end proposals aim at improving the performance of TCP using some form of selective acknowledgment (SACKs) to recover from multiple packet loss in a window of data. They also try to have the sender distinguish between loss due to congestion and other forms of losses using an Explicit Loss Notification (ELN) algorithm. Split connection approaches hide the wireless link by terminating the TCP connection at the base station. Such schemes use a separate connection between the base station and the destination host and can use techniques other than TCP to perform well over wireless links. Examples of these schemes are: Indirect TCP or Snoop protocol. Link layer proposals attempt to hide loss due to wireless links using local retransmissions and perhaps forward error correction over the wireless link. Examples of link layer protocols are forward error correction (FEC) and automatic repeat request (ARQ). Digital cellular systems, such as TDMA or CDMA, use ARQ protocols.

All solutions we have briefly described suffer serious drawbacks. In fact, in one case they violate the end-to-end paradigm, thus requiring complex implementation, or in the other case, they do not offer a remarkable throughput increment.

Another known problem of TCP is that it experiences a very low performance over connection with asymmetric bandwidth. These problems arise in several access networks, including bandwidth-asymmetric networks and packet radio subnetworks. In these cases, the TCP performance degrades significantly because of imperfection and variability in the ACK feedback from the receiver to the sender.

The present invention solves the problem of improving the fairness of TCP, the throughput of TCP over wireless connection and over connection with asymmetric bandwidth using an end-to-end approach. The present invention solves also other problems in real-time streaming of audio and video sources that are associated with

prior art.

## BRIEF SUMMARY OF THE INVENTION

It is a general object of the present invention to provide an end-to-end estimation of the bandwidth available in a client-server connection established over a packet switching network such as the Internet Protocol (IP) network. It is another object of the present invention to provide a method to perform congestion control in packet networks using this estimate.

The invention can be used within the Transmission Control protocol (TCP) to increase the utilization of network bandwidth. In particular it can be used to improve TCP performance over unreliable links such as wireless links in the Group Special Mobile (GSM), in the General Packet Radio Service (GPRS), in the 3G, 4G or Universal Mobile Telephone System (UMTS), and to increase the utilization of network bandwidth in the presence of connection with asymmetric bandwidth such as in the case of cable networks, (e.g. cable TV networks), direct broadcast satellite (e.g. an IP service using Digital Video Broadcast (DVB), with an interactive return channel), Very Small Aperture Satellite Terminals (VSAT), Asymmetric Digital Subscriber Line (ADSL), and several packet radio networks. These networks are increasingly being deployed as high-speed Internet access networks, and it is therefore highly desirable to achieve good TCP performance. The present invention also increases the fairness in bandwidth utilization.

The invention can be used over the User Datagram Protocol (UDP) to stream audio/voice using adaptive coding. With the term adaptive coding we mean that the quality of coding takes into account the estimate of the available bandwidth. An example is layered coding, in which the number of transmitted layers can be chosen by taking into account the estimate of available bandwidth.

The present invention can be used within an application conceived for real-time and running over the Real Time Protocol (RTP) that runs over the UDP protocol. The bandwidth estimate can be delivered from the receiver to the sender using the RTP Control Protocol.

The invention is based on obtaining samples of available bandwidth. When the invention is utilized for the TCP, samples are obtained at the sender side using the returning acknowledgment packets or at the receiver side using the arriving packets. Samples are continuously taken and are low-pass filtered. A filter with time-varying coefficients is used in order to obtain an estimate of available bandwidth. When samples of available bandwidth are computed at the receiver by considering the flow of arriving packets, and are filtered to obtain an estimate of the available bandwidth, then the bandwidth estimate is delivered to the sender using the Receiver Advertising Window field of the ACK packets. Estimation at the receiver is particularly suited for connections with asymmetric links.

The TCP sender utilizes the estimate to properly set congestion window and slow start threshold. In this way today's TCP blind reduction of the congestion window to half or to one after a congestion episode, i.e. after a timeout or 3 duplicate acknowledgments, is substituted by an *adaptive* setting of the congestion window and the slow start threshold. The adaptive setting takes into account the current estimate of the available bandwidth.

When the invention is used over the UDP protocol, the bandwidth estimate is performed at the receiver side and is sent back to the sender application using the RTP Control Protocol. The application at the sender utilizes the estimate to implement an

adaptive coding for audio/video streaming that takes into account the estimate of the available bandwidth.

The foregoing has outlined some of the more pertinent features of the present invention. Other features and a fuller understanding of the invention may be had by referring to the following Detailed Description of the Preferred Embodiment.

### BRIEF DESCRIPTION OF THE DRAWINGS

For a more complete understanding of the present invention and the advantages thereof, reference should be made to the following Detailed Description taken in connection with the accompanying drawings in which:

FIG. 1 is a representative system in which the present invention is implemented;

FIG. 2 is a representation of the bandwidth estimation algorithm implemented at the sender side of the connection;

FIG. 3 is a representation of the bandwidth estimation algorithm implemented at the receiver side of the connection;

FIG. 4 is a representation of the bandwidth estimation algorithm implemented at the receiver or at the sender side of a TCP connection;

FIG. 5 is a representation of the bandwidth estimation algorithm implemented at the receiver or at the sender side of a UDP connection.

### DESCRIPTION OF THE PREFERRED EMBODIMENT

A known Internet client-server system is implemented as illustrated in Fig. 1. A client machine 10 is connected to a server machine 14 via a network 12. For illustrative purposes, network 12 is the Internet, an intranet an extranet, a satellite network or any other wireless or wired network. A server machine 14 is accessible by clients, one of which is illustrated by client machine 10. A representative server is a computer comprising a processor, an operating system such as Microsoft Windows®, IBM OS/2®, Sun Solaris®, Unix, Linux, a Web server program such as Netscape Enterprise server®, Apache®, Microsoft Internet Information Server®. The server also includes an Application Program Interface (API) that allows an application developer to extend or customize some parameters of the transport layers such as the size of the socket buffers. The server can include application programs for audio/video streaming. The server can be a mobile server. The server can be part of a Global Hosting System such as the one developed by Akamai Company and described in the US Patent Number 6,108,703.

A representative client machine is a personal computer based on a processor such as Pentium®, Motorola® or RISC® processor that includes an operating system such as Microsoft Windows®, IBM OS/2®, Sun Solaris®, Unix, Linux, a Web browser such as Microsoft Explorer® or Netscape Navigator® and application programs such as Real Networks® or Windows Media Player®. A client may also be a notebook computer, a PDA, a mobile client such as a cellular phone or any other device connectable to the computer network via a wired or wireless link such as a wireless local area network (WaveLAN), a HyperLan, Bluetooth, GPRS, 3G, 4G or UMTS. The client-server connection can also be between mobile hosts such as cellular phones, or PDAs.

The present invention can be implemented in the TCP protocol suite of several

operating systems such as Microsoft Windows TCP, Sun Solaris TCP, or it can be implemented in applications running over the RTP/UDP protocol. Examples of these ones are applications that are designed for audio/video streaming such as Real Networks® or Windows Media Player®. The present invention could be used in a  
 5 Global Hosting System to dynamically choose the best server to satisfy the request of a client or to select the best route in a content delivery system such as the one described in the International Patent WO 00/38381 or in the US 6,006,264 patent or in other similar patents.

Fig. 2 depicts the algorithm for performing the bandwidth estimation at the sender side of the connection. The flow of packets 22 goes from the sender to the receiver. The flow of acknowledgment packets (ACKs) 20 goes from the receiver to the sender. This scheme, or other similar schemes that are based on a forward flow of data and on a backward flow of control data, is utilized for congestion control by protocol such as the TCP/IP protocol or the RTP Control Protocol or by other packet networks such as the  
 10 Asynchronous Transfer Mode (ATM) networks. The flow of returning acknowledgment packets 20 are utilized by the routine 26 to compute samples of available bandwidth and compute an estimate of available bandwidth.

For sake of clarity we explain the algorithm implemented in routine 26 in the case of TCP/IP protocol. However it is clear the algorithm can be easily generalized to any  
 20 other way of acknowledging packets (e.g. RM cells that are interleaved with data cells in ATM networks), the only difference being a proper counting of the number of packets that correspond to ACK packets.

In the case of the TCP protocol it is assumed that every packet is acknowledged or, if delayed acknowledgment is implemented, an ACK is sent every other packet. Therefore when an ACK packet reaches the sender it means that an amount of data  
 25 corresponding to one packet has been delivered to the destination or an amount of data corresponding to two packets has been delivered if a cumulative ACK is received due to delayed ACK.

Notice that when a duplicate ACK reaches the source it counts for one packet. Therefore a cumulative ACK counts only for the amount of one packet since duplicate  
 30 ACKs have been already taken into account. The only case when an ACK counts for two packets is when a cumulative ACK is received due to delayed ACK. Notice that if another algorithm of generating ACK packets is implemented, this particular algorithm must be considered to establish a correspondence between the ACK packets and the amount of data, i.e. packets, that have been delivered.

Each time the sender side receives an ACK at time  $t_j$ , a sample  $b_j$  of available bandwidth is computed as follows:

$$b_j = \frac{d_j}{t_j - t_{j-1}}$$

where  $t_{j-1}$  is the time the previous ACK was received and  $d_j$  is the amount of data that  
 40 have been acknowledged by the ACK.

Since congestion occurs whenever the low-frequency input traffic rate exceeds the link capacity, a low-pass filter is employed to average samples of available bandwidth and obtain the estimate of the available bandwidth. Notice that averaging is also critical to filter out "noise" due to delayed acknowledgements.

Thus, to obtain an estimate of the available bandwidth, the routine 26, which is represented in Fig. 2 by the block BWE, implements a discrete time low-pass filter. In particular we implement a low-pass filter with time-varying coefficients to counteract the fact that packet interarrival times are not constant. The implemented filter to obtain  
 45

the bandwidth estimate (BWE) is the following:

$$\hat{b}_j = \frac{2\tau_f - \Delta_j}{2\tau_f + \Delta_j} \hat{b}_{j-1} + \Delta_j \frac{b_j + b_{j-1}}{2\tau_f + \Delta_j}$$

where  $\hat{b}_j$  is the filtered measurement of the available bandwidth (i. e. the estimate BWE) at time  $t = t_j$ ,  $\Delta_j = t_j - t_{j-1}$ , and  $1/\tau_f$  is the cut-off frequency of the filter. A key feature of filter is that it contains time-varying coefficients.

The filter has a cut-off frequency equal to  $1/\tau_f$ . A typical value is  $\tau_f = 1\text{sec}$ . Since the ACK stream is asynchronous and cannot guarantee the constraint of the Nyquist sampling Theorem, we establish that if a time  $\tau_f/m$  ( $m \geq 2$ ) has elapsed since the last received ACK without receiving any new ACK, then the filter assumes the reception of a *virtual* sample  $b_j = 0$ . Thus, in the persistent absence of ACKs since time  $t = t_j$ , the filter takes the form:

$$\hat{b}_{j+h} = \left( \frac{2m-1}{2m+1} \right)^h \hat{b}_j, h \geq 2$$

that is, in the persistent absence of ACKs, the estimated bandwidth geometrically goes to zero.

Fig. 3 depicts the case when the bandwidth estimation algorithm 30 is executed at the receiver side of the connection. In this case the receiver does not need to determine the amount of delivered data that corresponds to the ACK packets because the receiver directly knows the amount  $d_j$  of received data. Therefore it can easily compute bandwidth samples and estimate the bandwidth using the low-pass filter described above in the present invention. The estimated bandwidth is sent to the sender using ACK packets. In the case of TCP, it can be used the Receiver Advertising Window field via the following setting:

$$\text{Advertised\_Window} = \min(\text{Advertised\_Window}, RTT_{\min} \times BWE)$$

where  $RTT_{\min}$  is the minimum round trip time, that is, it is the round trip propagation time and the bandwidth estimate BWE is measured in packets/sec or bytes/sec.

The implementation of bandwidth estimation at the receiver is utilized in the presence of connections with asymmetric bandwidth, in which the bandwidth available for the backward flow of control cells is much smaller than the bandwidth of the forward path. This choice has the major advantage that bandwidth estimation is robust respect to losses of ACKs along the backward path. Moreover, to optimize the performance, the Receiver Socket buffer 46, see Fig. 4, must be not greater than the bandwidth of the link, which connects the client to the network, times  $RTT_{\min}$ .

Fig. 4 shows the bandwidth estimation algorithm 42 implemented within the TCP protocol at the sender side or implemented at the receiver side 44.

Notice that when the bandwidth estimation algorithm is implemented at the sender side, it is triggered by reception of ACKs. In this case it is necessary to compute the amount of delivered data that corresponds to the ACK by considering the algorithm employed to generate the ACK (i. e. delayed ACK, selective ACK etc.) as described above. The pseudo-code of the algorithm is:

```
if (an ACK is received at time  $t_j$ )
    compute the bandwidth sample
```

$b_j = (\text{amount of data}) / (t_j - t_{j-1})$

compute an estimate  $\hat{b}$  of the available bandwidth using the filter

$$\hat{b}_j = \frac{2\tau_f - \Delta_j}{2\tau_f + \Delta_j} \hat{b}_{j-1} + \Delta_j \frac{b_j + b_{j-1}}{2\tau_f + \Delta_j}$$

endif

5

When the algorithm is implemented at the receiver side, it is triggered by the reception of packets. The pseudo-code of the algorithm is:

if (a packet is received at time  $t_j$ )

10 compute the bandwidth sample

$b_j = \text{packet\_size} / (t_j - t_{j-1})$

compute an estimate of the available bandwidth using the filter

$$\hat{b}_j = \frac{2\tau_f - \Delta_j}{2\tau_f + \Delta_j} \hat{b}_{j-1} + \Delta_j \frac{b_j + b_{j-1}}{2\tau_f + \Delta_j}$$

endif

15

The algorithm for estimating the available bandwidth described in the present invention is used for setting the amount of data for unit of time that is injected by the sender.

20 In the case of TCP, the estimated bandwidth is used to set the congestion window and the slow start threshold after a congestion episode is experienced at the end of the TCP probing phase (called additive increase phase), that is, after a timeout or the reception of  $n$  (typically 3) duplicate acknowledgments. The rationale of this strategy is simple. TCP sets a slow start threshold and congestion window, which are related to the network capacity measured at the time congestion is experienced. In particular, this invention avoids the current TCP blind reduction of the congestion window to half or to one after congestion (which is called multiplicative decrease) by implementing an *adaptive decrease* that takes into account the bandwidth available at the time of congestion. The advantage of the proposed algorithm is that the TCP sender recovers faster after losses especially over connection with large round trip time or containing

25 wireless links where sporadic losses are due to unreliable links and not to congestion. Simulation results have shown remarkable throughput increment up to 1200% in comparison with TCP Reno over wireless connection experiencing fading and blackouts.

30 The way the congestion window is increased during slow start phase and congestion avoidance phase can be left unchanged, that is it increases exponentially and linearly, as in current TCP Reno, to probe network capacity or it can be modified to take into account the bandwidth estimate.

35 The present invention utilizes the estimated bandwidth (BWE) to set the congestion window (*cwnd*) and the slow start threshold (*ssthresh*) after a congestion episode.

40 The general form of the algorithm after  $n$  (typically  $n=3$ ) duplicate ACKs is described by the following pseudo-code:

after  $n$  duplicate ACKS

45 if (*cwnd* > *ssthresh*) /\* congestion avoidance phase \*/  
 $ssthresh = f_1 (BWE * RTT_{min})$

```

    cwin=ssthresh
    endif
    if (cwnd<ssthresh) /*slow start phase*/
    ssthresh=  $f_2(BWE \cdot RTT_{min})$ 
5      if (cwnd > ssthresh)
        cwnd= ssthresh
      endif
    end if

```

10 The rationale of the algorithm is simple. When  $n$  DUPACKS are received, it means that we have hit network capacity. Thus the slow start threshold is set equal to the available pipe size, which is  $BWE \cdot RTT_{min}$ . The congestion window is set equal to the ssthresh and the congestion avoidance phase is entered again for gently probing new available bandwidth. Function  $f_1$  introduces one degree of freedom that can be used to tune the algorithm. Here we choose an identity function for  $f_1$ .

15 During slow start phase we are still probing for the available bandwidth. Therefore the BWE we obtain after  $n$  duplicate ACKS is used to set the slow start threshold. After *ssthresh* has been set, the congestion window is set equal to the slow start threshold only if it results  $cwin > ssthresh$ . In other words during slow start we do not speed up the increasing of *cwin* but we let it be exponential as in current TCP Reno. 20 Function  $f_2$  introduces one degree of freedom that we can use to tune the algorithm. We choose  $f_1(\cdot) = f_2(\cdot) = \max(2, BWE \cdot RTT_{min})$ .

The algorithm after coarse timeout expiration is:

```

25 After timeout expiration
    if (cwin>ssthresh) /* congestion avoidance phase*/
    ssthresh=  $f_3(BWE \cdot RTT_{min})$ 
      if (ssthresh < 2) ssthresh = 2;
30      cwnd = 1 (or cwnd=2);
      else
        cwnd=  $f_4(BWE \cdot RTT_{min})$ 
      endif
    endif
35    if (cwin<ssthresh) /* slow start phase*/
    ssthresh=  $f_5(BWE \cdot RTT_{min})$ 
      if (ssthresh < 2) ssthresh = 2;
      cwnd = 1 (or cwnd=2);
      else
40      cwnd =  $f_6(BWE \cdot RTT_{min})$ 
      end if
    end if

```

45 The rationale of the algorithm is again simple. After a timeout the *cwnd* and the *ssthresh* are set in according with one of the functions  $f_i$  ( $i=3,6$ ) of  $BWE \cdot RTT_{min}$  depending on the phase the algorithm was in when timeout was experienced.

Notice that using general functions  $f_i$  ( $i=1,6$ ) gives six degree of freedom to tune the algorithm.

One of the possible implementation is obtained choosing very simple functions  $f_i$ .

*Algorithm after 3 duplicate ACKS*

After 3DUPACKS

```

5  ssthresh= (int)((current_bwe_/size_/8) * RTTmin);
   if (ssthresh < 2)
     ssthresh = 2;
   endif
   /* during slow start we do not increase CWIN if it is smaller than ssthresh */
10  if (cwnd> ssthresh)
     cwnd= ssthresh;
   endif

```

As can be viewed by the code, the function  $f_1$ , which is used to set *ssthresh* when 3 DUPACK are received during congestion avoidance, is simply chosen as an identity function  $f_1(x)=x$ .

*Algorithm after timeout expiration*

```

20  After TIMEOUT:
     ssthresh_ = (int)((current_bwe_/size_/8) * RTTmin);
     if (ssthresh < 2)
       ssthresh = 2;
     endif
25  cwnd = 1 or cwnd=ssthresh;

```

The function  $f_1$  can be tuned in little different ways. However the essence of the tuning is that the control window *cwnd* and *ssthresh* are set equal to the estimated bandwidth BWE times the minimum RTT.

30 The invented bandwidth estimation algorithm is the best candidate to take full advantage of Active Management Queue algorithms such as Random Early Discard (RED) or weighted (WRED). In fact, using active droppers or markers, it is possible to allocate available bandwidth to different flows in according to specified policies. It is clear that BWE estimation allows a TCP connection to easily track the bandwidth allocated to the connection by the droppers.

35 The same algorithm of bandwidth estimation is proposed to enhance the delivery of packets over the UDP protocol. Examples are video and audio (real-time) streams over UDP or over other protocols such as the Real Time Protocol (RTP) as it is shown in Fig. 5. In Fig. 5 the algorithm 52 of bandwidth estimation described above is executed at the receiver. The bandwidth estimate BWE is sent to the application 50 using control packets. The application utilizes the BWE to implement adaptive coding that takes into account available bandwidth. In this case the BWE information is used to choose a corresponding level of quality for the coding of audio or video signals. For example the application can utilizes layering coding and can send over the UDP protocol 54 the number of layers that are allowed by the estimated available bandwidth.

45 The source input rate follows a probing phase during which the rate is increased by following a staircase like function, that is, a step-by-step increment. Each step of the increment corresponds to an increment of the quality of coding, for instance it corresponds to transmit another layer of a layered coding. The amplitude of each step

can be different and it depends on the particular coding technique that is used. The first value of the input rate on the staircase input rate function corresponds to the minimum bandwidth that is required to transmit the stream. For example, let  $q_1, q_2, q_3, \dots, q_n$ , be the input rates corresponding to different quality of coding, then the input rate starts from  $q_1$  and is increased, step-by-step, each time an RTP control packet is received that confirm that there is no congestion. After that a congestion episode is signaled by an RTP control packet, the input rate is set equal to the value  $q_i$  that corresponds to the greatest quality of coding with a rate less than the estimated available bandwidth. The estimated bandwidth is computed at the receiver and sent back using RTP control packets. After this setting the increasing phase of the input rate is entered again through the steps  $q_i, q_{i+1}$ , in order to probe for extra available bandwidth. Notice that the increasing phase follows a step-by-step fashion, where the amplitude of the steps derives from the particular coding that is used.

## CLAIMS

1. An end-to-end estimation of the bandwidth available in a client-server connection established over a packet switching network, comprising:

a routine to compute samples of available bandwidth by taking into accounts the flow of packets received by the client, if the routine is implemented at the receiver side, or by taking into accounts acknowledgment packets received by the sender, if the routine is implemented at the sender side;

a routine that implements a discrete time low-pass filter to obtain a filtered value of the samples of available bandwidth.

2. The end-to-end bandwidth estimation according to claim 1, wherein a sample of available bandwidth  $b_j$  at time  $t_j$  is computed as:

$$b_j = \frac{d_j}{t_j - t_{j-1}}$$

where  $d_j$  is the amount of data that have been received at the receiver or acknowledged at the sender in the interval  $t_j - t_{j-1}$ ,  $t_{j-1}$  is the time when the previous ACK was received by the sender or the time when the previous packet was received by the receiver, and  $t_j$  is the time when the current ACK is received by the sender or when the current packet is received by the receiver.

3. The end-to-end bandwidth estimation according to claim 1, wherein the routine implements a discrete time low-pass filter with time-varying coefficients.

4. The end-to-end bandwidth estimation according to claim 1, wherein the routine implements the discrete-time low-pass filter with time-varying coefficients:

$$\hat{b}_j = \frac{2\tau_f - \Delta_j}{2\tau_f + \Delta_j} \hat{b}_{j-1} + \Delta_j \frac{b_j + b_{j-1}}{2\tau_f + \Delta_j}$$

where  $\hat{b}_j$  is the filtered measurement of the available bandwidth at time  $t = t_j$ ,  $\hat{b}_{j-1}$  is the filtered measurement of the available bandwidth at time  $t_{j-1}$ ,  $\Delta_j = t_j - t_{j-1}$ ,  $1/\tau_f$  is the cut-off frequency of the filter,  $b_j$  is the sample of the available bandwidth at time  $t_j$ , and  $b_{j-1}$  is the sample of the available bandwidth at time  $t_{j-1}$ . If a time  $\tau_f/m$  ( $m \geq 2$ ) has elapsed since the last received ACK or packet without receiving any new ACK or packet, then the filter assumes the reception of a *virtual* sample  $b_j = 0$ .

5. Method for adapting the amount of data for unit of time, i.e. the rate, sent by the server to the client over a packet network, comprising an end-to-end bandwidth estimation according to claim 1.

6. Method for adapting the amount of data for unit of time sent by the server to the client according to claim 5, wherein the low pass filter is a low pass filter according to claim 3 or 4.

7. Method for adaptively setting congestion window and slow start threshold in the TCP/IP protocol, comprising an end-to-end bandwidth estimation according to claim 1.

8. Method for adaptively setting congestion window and slow start threshold in the TCP/IP protocol according to claim 7, wherein the low pass filter is a low pass filter according to claim 3 or 4.

9. Method for adaptively selecting the quality of coding, or the numbers of layers to be transmitted in a layered coding of an audio/video source using the TCP protocol, or the UDP protocol or the RTP protocol, comprising an end-to-end bandwidth estimation according to claim 1.

10. Method for adaptively selecting the quality of coding, or the numbers of layers to be transmitted in a layered coding of an audio/video source using the TCP protocol, or the UDP protocol or the RTP protocol according to claim 9, wherein the low pass filter is a low pass filter according to claim 3 or 4.

5 11. Method for adaptively selecting the quality of coding, or the numbers of layers to be transmitted in a layered coding of an audio/video source according to claim 9 or 10, comprising:

10 increasing step by step the quality of coding, or the numbers of layers to be transmitted in a layered coding of an audio/video source until congestion is experienced by means of control packets;

setting the quality of coding or select the numbers of layers to be transmitted after that a congestion episode is signaled by means of control packets in according with the bandwidth estimation according to any of claims 1 to 4;

15 increasing again step by step the quality of coding or the numbers of layers to be transmitted in a layered coding to probe for extra available bandwidth.

12. Method for setting the Advertised Window of TCP equal to the minimum of the Advertised Window and the bandwidth estimate times the minimum round trip time, wherein the samples are computed according to claim 1 or 2, and the bandwidth estimate is computed according to any of claim 1, 3 or 4.
